ZFit and multiple impedance diagrams fitting

I – INTRODUCTION
Electrochemical impedance spectroscopy (EIS) measurements are widely implemented in all fields of electrochemistry (e.g. energy and corrosion application). The impedance diagrams are usually fitted using equivalent electrical circuits (EC) [1-3]. Variations of EIS measurements are frequently linked with physical parameters, like the potential or temperature. This behavior results in the variation of the EC parameters values. The analysis of EIS measurements at different conditions becomes important to understand system of interest’s physical behavior [1, 2].

In this context, EC-Lab® provides a powerful and user-friendly tool to fit successive EIS diagrams called ZFit. ZFit automatically determines (and plots) successive values of EC components for a series of impedance diagrams. This advanced feature would allow the user to model experimental results [4].

SPEIS and SGEIS techniques allow the user to perform successive impedance measurements. The Application Note # 17 describes the use of SPEIS technique and ZFit [5] tools in order to fit the presented EIS diagram.

This note explains the use of ZFit to adjust the component values of EC, for several impedance diagrams. The different options to fit several EIS diagrams are also presented. Examples in batteries, photo-voltaic cells and corrosion application are shown to illustrate the functionalities of ZFit.

II – FITTING MULTIPLE IMPEDANCE DIAGRAMS
ZFit allows choosing an equivalent circuit in a list of predefined circuit or editing a new EC if it is not in this list1. Equivalent Circuit edition windows of ZFit is shown in Fig. 1.

In order to fit multiple EIS graphs, the user must first, select (or create) the EC in the Equivalent Circuit block, and choose Select “all” cycles in the ZFit windows (Fig. 2) in the Fit block.

ZFit provides three minimization algorithms: Randomize, Simplex and Levenberg-Marquardt. The user can combine Randomize with Simplex or Levenberg-Marquardt. Using Randomize option is better to provide automatically suitable initial values for further minimizations. If Randomize + Simplex or Randomize + Levenberg-Marquardt option is selected, the Randomize minimization could be performed on the first cycle only or on every cycles. If the parameters are close (between the successive cycles), it is recommended to use the Randomize option only in the first cycle. The user can choose the maximum number of Randomization iterations.

---

1 ZFit has 13 components to build the equivalents circuits. Among them, there are the specific electrochemical elements, such as W6 (diffusion-convection) or M (restricted linear diffusion).
The evolution of fitted EC parameters are automatically displayed in a new graph.

III – EXPERIMENTAL RESULTS

III - 1 Li-ION BATTERIES APPLICATION: SOC AND SOH

EIS technique was used to study batteries state of charge or state of health (SOC or SOH). EIS appears as a non-destructive, fast and easy-to-use technique. The variation of EIS diagrams (EC parameters) would enable the determination of SOC and SOH [2]. In the present note, the EIS measurements on a commercial Li-ion battery are presented (nominal capacity 2.4 Ah). The EIS diagrams were analyzed using ZFit.

The Nyquist diagrams were obtained using PEIS protocol (Fig. 3). Each diagram was measured after a discharge at C/10 rate for 30 min, followed by 10 min at open circuit potential, OCV (GCPL technique). One can observe the two typical capacitive circle arcs at high and middle frequencies (attributed respectively to the solid electrolyte interphase (SEI) and the charge transfer). At low frequencies one can highlight a diffusion region.

The EIS graphs have been fitted with the EC: L1+R1+Q2/(R2+Q3/R3)+Q4 (Fig. 4). The results of the fitting process are also shown in Fig. 3.

Figure 2: ZFit window.

Figure 3: Results of fitting process with ZFit.

Figure 4: Equivalent circuit used to fit the experimental result from Fig. 3.

As mentioned above, one can use ZFit to study the evolution of EC parameters. Fig. 5 shows the evolution of internal resistance R1, SEI and...
charge transfer associated resistances (R_2 and R_3, respectively) with the potential.

![Graph showing evolution of R_1, R_2, and R_3 with potential](image)

**Figure 5:** Evolution of R_1 (□), R_2 (○) and R_3 (△) with the potential.

In the battery field, those values are valuable to characterize and further to determine batteries state of charge (SOC) or state of health (SOH) [1-3, 5].

**III - 2 PHOTOVOLTAIC CELLS APPLICATION**

Silicon solar cells can be characterized by plotting polarization curves and measuring impedance at several points of the curve [6, 7].

The photovoltaic cell (PV) was characterized under white-LED constant illumination. The EIS measurements have been performed under potential control (SPEIS technique) between 0 and 3.8 V every 200 mV. The results of these measurements are shown in Fig 6.

![Graph showing SPEIS measurements on a PV cell](image)

**Figure 6:** Results of SPEIS measurements on a PV cell.

These EIS graphs can be, in a first approximation, fitted by a R/C circuit. The evolution of the resistance with the potential is shown in Fig.8. R_1 value reaches a maximum value at 2.6 V.

**Figure 8:** Evolution of resistance R_1 with the potential.

**III - 3 CORROSION: POLARIZATION RESISTANCE EVOLUTION AS A FUNCTION OF TIME**

The corrosion current can be determined by measuring the polarization resistance, (Rp), at the corrosion potential by using the Stern-Geary relationship [9, 10]. Stationary (voltammetry at low scan rate) or dynamic measurements (EIS) can be performed to determine the Rp value.

The corrosion rate variations, as a function of time, are particularly useful in chemical industry to evaluate for instance the influence of experimental conditions in a reactor (addition of a reagent, temperature, etc.).

In this note, we present the EIS measurements performed (under potential control) on AISI 108 steel sample in 0.5 M H_2SO_4. The electrode surface was slightly passivated applying 1V Vs SCE during 1 s. EIS measurements were done at the corrosion
potential. The EIS diagrams obtained are shown in Fig 9. The EC: La1+R1+C2/R2 was used to fit the experimental results (where R2 corresponds to Rp) (Fig.10).

Figure 9: EIS measurements on AISI 108 steel sample (blue points) and results of fitting process with ZFit (dashed red line).

Figure 10: Equivalent circuit use to fit the experimental result from Fig. 9.

Figure 11 shows the evolution of Rp during the passivation process. One can observe the non-monotonic variation of Rp with the cycle number (equivalent to time). Between the first and third cycle, the Rp value decreases. Then, the value increases up to the twelfth cycle. After that, the Rp value slightly decreases.

Figure 11: Evolution of the polarization resistance with the number of cycles (time).

IV – CONCLUSION

Successive EIS measurements were performed in different application fields. After choosing an equivalent electronic circuit, ZFit allows in all those cases to study the evolution of EC components values. Those EC component values variations ease the identification of evolution’s empirical laws. Those empirical laws could be compared later on with theoretical laws.
